FOREWORD

This report, by the Geophysics and Aerospace Division of Allied Research Associates, Inc., Concord, Massachusetts, presents the results of a study of optimal processing of Nimbus II data for the observation of sea surface temperature patterns and their synoptic changes. These studies were performed for the Earth Resources Survey Program of the National Aeronautics and Space Administration under Contract NASW-1651. The Spacecraft Oceanography Project of the U.S. Naval Oceanographic Office was requested by NASA to act as monitor for this contract.

A separate publication, Bibliography on the Use of Satellites for Oceanographic Observations, was published in April of 1968 under this same contract.

Section 4 of this report was prepared by Mr. Willand, who was primarily responsible for the programming efforts during this study. Mr. Chang conducted the studies of manned observations from spacecraft, which are presented in Section 8.

The authors wish to acknowledge the assistance of Mr. William Bandeen of the NASA, Goddard Space Flight Center in obtaining the basic Nimbus data reduction programs. We also wish to acknowledge the kind assistance and cooperation of Mr. Joe Johns of the National Space Science Data Center in the development and operation of the modified programs. Mr. Larry McMillan of Allied Research Associates, Inc. is primarily responsible for the development of the Digital Color Printer used extensively in this study.

ABSTRACT

This report presents the results of a study of the optimal processing of satellite data for the observation of sea surface temperature patterns and their synoptic changes. Nimbus II data are used extensively. A two-phase approach is taken, using multi-spectral low resolution data for the development of data processing techniques, and single spectral region high resolution data for the actual observation of sea surface temperature patterns. Particular emphasis is placed on the Gulf Stream region. Individual topics discussed in this report include the following:

1. Modifications of the Nimbus data reduction programs to permit immediate mapping of only clear-sky data.
2. Development of techniques for day and nighttime automated cloud discrimination.
3. Preparation of recommendations on optimum data processing and analysis methods for routine operational measurement of sea surface temperature patterns on a near real-time basis.
4. Feasibility and parametric design studies with regard to sea surface temperature observations from manned satellites.
5. Development of a time history of Gulf Stream meander movement.

It was determined that for the optimal detection of cloud contamination in daytime cases (including high thin cirrus), a combination of visible and water vapor absorption radiation data should be used. For the Nimbus data, a 15% albedo threshold and a 237°K temperature threshold (in the water vapor absorption band) were established. Further refinement of threshold levels and cloud radiation characteristics can and should be accomplished using observations from manned spacecraft. For nighttime data, only the water vapor absorption data is available for cloud discrimination, although temperature limits may be placed on the IR data themselves. Computer programs were written to automatically apply these threshold criteria, and to map single or multiple pass clear sky data. An application of Monte Carlo statistical programs utilizing a world-wide cloud data bank revealed that observation of rapidly changing transient oceanographic phenomena may not be feasible under certain climatic conditions. Graphs are presented for the Gulf Stream area relating area coverage and the probability of obtaining that coverage as a function of the number of passes.

Gulf Stream meander movements for the month of October 1966 as determined from the Nimbus II HRIR (High Resolution Infrared) data were somewhat slower than anticipated, but are believed to be accurate. Near-shore meanders seemed to move at a rate of about 8 n. mi. per day while those larger meanders toward the northeast moved more slowly at about 4 to 5 n. mi. per day.

Because it is beyond the present state-of-the-art to automatically include atmospheric attenuation effects on any large scale basis, it is recommended that only the temperature gradient information be used in conjunction with conventional shipboard measurements. For rapid interpretation of resultant sea surface temperature maps in research applications, automatically generated color coded analyses are recommended.

1. INTRODUCTION

1.1 The Importance of Sea Surface Temperature Data

The temperature of the ocean's surface is the one oceanographic parameter most readily measured from a space platform. As such, its measurement will be a primary goal in the first flights of any program of Earth Resources Survey from space (Newell, 1968). This emphasis on sea surface temperature is well placed in that nearly all of man's sea-oriented activities, including fisheries, civil applications, and the military rely to some extent upon knowledge of the sea surface temperature patterns and their variation with time.

Fisheries

Correlations between water temperature and the behavior and occurrence of fish have been found (Hela, 1962). Particularly important is the location and estimation of intensity of upwelling which brings cold nutrient-rich bottom water to the ocean's surface. Important fishing grounds for pelagic fish are often found at the confluence or divergence of oceanic currents. From the surface temperatures, the pelagic fish population and their migrations may also be inferred. Fisheries already use analyses and forecasts of surface temperature for the prediction of spawning times, their location, and for estimation of the survival rate of the larvae (Wolff, 1965).

Civil Applications

In recent years the problem of sea-air interaction has gained increasing attention because of its importance in the better understanding of both the oceanic and the atmospheric circulations and their relation to weather prediction. The long-term prediction aspect of sea surface temperature has been emphasized by Namias, (1963) and others. The synoptic analyses and forecasts of sea surface temperature are finding greater use in synoptic meteorology through inclusion of heat exchange effects in forecasting models. Furthermore, sea surface temperature is required in the estimation of changes of surface air properties over the ocean, in wave forecasting for shipping, and in prediction of visibility, fog probability, and icing conditions. Various investigators (Fisher, 1958) have demonstrated direct correlations between the sea surface temperature and such meteorological phenomena as the growth and travel of hurricanes, and extratropical cyclonic development.

Military

In publishing the results of its 1965 meetings, the Panel on Oceanography of the President's Science Advisory Committee made the following statement; "The importance to Anti-Submarine Warfare of a continuing, effective program to study and characterize the ocean environment in which its equipment is designed to operate cannot be overstated." (Panel on Oceanography, 1966). One such property of the ocean environment is the sea surface temperature. It is used as an input to mathematical models for the prediction of the subsurface temperature structure, which in turn greatly affects the propagation of sound.

1.2 Benefits of Satellite Systems

The obvious advantage of satellite monitoring of surface temperatures is the vastly increased coverage available, both in space and in time. For fisheries this could mean the discovery of new fishing areas, and the ability to proceed directly to a fishing area, thereby eliminating many hours of fruitless searching. Assuming that space oceanography will be able to provide the data essential to the world-wide regulation of fisheries, it has been estimated that the potential economic benefits to the United States by 1975 would be \$75 to \$215 million (General Electric, 1967). As might be expected, the economic benefits which could result from improved long-range forecasting of marine weather systems are enormous. Apart from such sea-related activities as shipping, or the prediction of fog and icing conditions, the National Academy of Sciences has estimated that the potential benefits to farming, construction, recreation, etc. would exceed \$2 billion (N.A.S., 1965). For the military, the real-time aspects of satellite measurement programs would be the most important. A satellite carrying infrared sensors in a sun synchronous orbit would provide twice-daily global coverage of the world's oceans. To accumulate a sufficient data base to generate meaningful sea surface temperature (SST) analyses, the Fleet Numerical Weather Facility (FNWF) in Monterey, California currently must average 3-1/2 days of conventional surface ship data (Wolff, 1965a). The melding of these surface ship data with satellite temperature measurements would represent a significant step toward the real-time mapping of sea surface temperature patterns on a global scale.

1.3 Philosophy of Present Study

The optimal sea surface temperature measurement platform would be a near-polar orbiting sun synchronous satellite with a cross track scanning high resolution (better than 6 mi.) multi-spectral radiometer. Recommended spectral regions include a clean atmospheric window, a visible albedo channel, and a clean water vapor absorption band. The presence of the visible and water vapor bands would make possible the immediate flagging of cloud contaminated temperature data for day and nighttime passes (see Section 5). For the present study, which involved both the development of optimal data processing techniques and oceanographic studies per se, no such system was available. The most applicable data were those obtained by the Nimbus II radiometers.

The Nimbus II single channel High Resolution Infrared Radiometer (HRIR) operated in the 3.5 to 4.1 μ m window region. The spatial resolution is approximately 5 n.mi. at the subpoint. Because of contamination by reflected solar radiation, these data are generally usable only at night. The HRIR data have the spatial resolution required for meaningful surface temperature analyses, but because of the single spectral region, they provide no means for the automatic discrimination of cloud contamination.

The five channel Medium Resolution Infrared Radiometer (MRIR) operated in the following spectral regions:

Channel 1	6.4 to 6.9 μ m	water vapor absorption
Channel 2	10 to 11 μ m	atmospheric window
Channel 3	14 to 16 μ m	CO ₂ absorption
Channel 4	5 to 30 μ m	long wavelength infrared
Channel 5	.2 to 4.0 μ m	visible.

The spatial resolution of all MRIR channels is approximately 30 n.mi. at the subpoint. The MRIR data are thus of such low resolution that they preclude observation of detailed surface patterns. They do, however, permit the development and application of cloud discrimination techniques. As a result, the two broad areas of data processing and data applications had to be treated separately.

In developing data processing techniques, the MRIR data were used. Day and nighttime cloud discrimination as well as composite mapping programs were developed for the Nimbus data, although little oceanographic interpretation was made of the resultant analyses. The HRIR data were used to develop a time history

of the Gulf Stream for the month of October, 1966. In the development of these cases, the experience of the researcher in distinguishing cloud forms in the HRIR analog data had to be relied upon to indicate cloud contamination. This can certainly not be considered an optimal data processing technique. The details and the results of these and other aspects of the present study are given in Sections 3 through 8. The following section presents a brief review of the results of previous investigations.

2. PREVIOUS STUDIES

The work which had been done prior to the current study may be divided into two phases. Phase I was largely the experimental stage, looking into the feasibility of using satellite data for sea surface temperature measurement, and uncovering some of the problems which would have to be solved (Greaves, 1965). During Phase II, data processing techniques were developed to cope with some of these problems, and recommendations and suggestions were made for gathering and processing large amounts of data from future satellite systems (Greaves, 1967).

2.1 Phase I

Using data from the TIROS VII satellite, the results of our initial studies confirmed that satellite infrared data could provide accurate measurements of sea surface temperature gradients. In the absence of surface ship conventional measurements to serve as ground truth data, good absolute temperature values were generally unattainable. This was due largely to uncertainties in atmospheric attenuation and in the calibration and degradation of the TIROS radiometers.

A critical problem which was uncovered is the detection and elimination of data points where clouds prevent an uncontaminated view of the sea surface. It was found that the usual sources of cloud cover information such as conventional meteorological observations and satellite TV data, were insufficient for determining all of the clear areas useful for satellite temperature measurements. Hand analysis indicated that by using the radiometric data themselves, particularly the Channel 5 sensor in the visible portion of the spectrum (0.55-0.75 μ m), clear areas could be detected in the daytime data on a point by point basis. Due to the relatively low resolution of the TIROS radiometer (approximately 30 n. mi. at the subpoint), regions of scattered cloud still presented difficulties, as the data represent averages over the entire scan spot.

For the nighttime data, it was determined that the TIROS radiometers were not sufficiently capable of accurately locating cloud-free areas. The primary cause of the failure in this case seems to have been the relatively high noise level in the basic data. Using daytime data, apparent cloud contaminated areas were determined using various nighttime cloud discrimination techniques. These areas were then compared with those indicated by the visible channel data. In general, little dependable correlation could be found.

At the close of Phase I, it seemed evident that for effective further use of the TIROS radiation data, modifications of the existing data reduction computer programs would be required. These modifications were subsequently carried out during the Phase II studies.

2.2 Phase II

During the Phase II studies two basic modifications were made to the existing TIROS VII data reduction programs. One change permitted the automatic listing (and ultimate mapping) of only the cloud free daytime data. The clear-cloudy decision for each data point was made on the basis of the corresponding visible channel data. Before thresholds could be established, it was first necessary to convert the visible channel data to the albedo format to eliminate the dependence on solar zenith angle. The second basic modification enabled the researcher to composite the clear sky data from more than one Final Meteorological Radiation Tape (FMRT) onto a single tape for subsequent mapping. The intended goal in this case was to experiment with the composite mapping program to seek optimal data averaging and processing techniques.

The first of the two programs outlined above was used successfully, although the time consuming task of analyzing the resultant temperature maps remained. In addition, the inability to distinguish cloud contamination in the TIROS nighttime data meant the effective loss of 50 percent of the recorded data. While the second program was successful operationally, there was little occasion to use it due to the poor orbital and scanning geometry characteristics of TIROS VII. Daytime passes over a given area on consecutive days where the scanning mode was usable, and the nadir angles sufficiently small, were extremely rare. Moreover, due to the variable nature of the sea surface temperature patterns, compositing data from passes which are widely separated in time can produce only gross scale average patterns.

Because of these limitations of the TIROS system, it was recommended at that time that future work be done using data from an earth oriented, sun synchronous satellite system such as Nimbus II. The remaining sections of this report describe at length the development of data processing techniques for the Nimbus II radiation data, and provide some examples of the use of these data.

3. THE BIBLIOGRAPHY

The Statement of Work of the current contract called for the development of a comprehensive bibliography on the general subject of remote sensing of oceanographic parameters, with particular emphasis on satellite measurements of sea surface temperatures. This bibliography entitled, Bibliography on the Use of Satellites for Oceanographic Observations was published in annotated form under separate cover in April 1968 (Widger, 1968).

The bibliography provides all identifiable, significant citations pertinent to the use of satellites specifically for oceanographic observations, with some emphasis on observations of sea surface temperature. Because many discussions of remote sensing of oceanographic parameters from other observing platforms, particularly aircraft, have direct pertinence to potential satellite observing techniques, many of the entries fall into this category. This is especially true in the case of infrared observations of sea surface temperature.

The bibliography does not, with certain limited exceptions, include entries on oceanography that are not directly pertinent to satellite observing techniques. Such more general oceanographic items can be located through the several general bibliographies on oceanography that already exist. Neither does it, in general, include entries solely pertinent to satellite observations of meteorological conditions over the oceans, since such material can be found in the several bibliographies on the "Use of Satellites in Meteorology" published by the American Meteorological Society in its Meteorological and Geostrophysical Abstracts. These bibliographies are, however, specifically cited.

Abstracts are included for each entry for which they were available, either from the cited document itself or from its citation in other abstracting or bibliographic publications.

PRECEDING PAGE BLANK NOT FILMED.

4. COMPUTER PROCESSING

As indicated in Section 2.2, the difficulties with the TIROS orbital and scanning geometries, together with the low resolution and generally high noise level of the TIROS data led to the recommendation of using a more advanced satellite configuration. The Nimbus II satellite, while it does not combine the desirable features of high resolution and cloud discrimination ability into a single sensor, it does possess these features in separate data gathering systems. This section describes the programs which have been derived for the optimal usage of the Nimbus II data. Complete listings of these programs have been provided in Appendix A.

Currently, Nimbus II HRIR and MRIR data may be ordered in a variety of formats from the National Space Science Data Center (NSSDC) at Goddard Space Flight Center (GSFC), Greenbelt, Maryland. The various formats available, and the ordering procedures are available in the Nimbus II User's Guide (ARACON Geophysics Company, 1966).

We feel that the modifications of these basic programs made in the course of this study are sufficiently general, and applicable to a variety of research efforts that they should be made readily available to other researchers. We strongly recommend, therefore, that the existence of these programs be made known to the potential users, and that their use be made a standard option which may be requested from NSSDC. As will be seen, the basic operating procedures do not differ from those currently used.

4.1 Original Programs.

The Unified Nimbus HRIR and MRIR Mercator Map Programs were originally developed by NASA to map recorded experimental data for a selected area on the earth, and within a chosen time span. These data were first measured by the Nimbus radiometers and recorded on the Nimbus Meteorological Radiation Tapes (NMRT).

The experimental data are printed at grid points on a mercator projection of a specified geographical region. A grid point map indicating the number of measurements associated with each grid point is also produced. Any non-polar geographic region (up to approximately 70° North or South latitude) can be displayed

at any scale factor by this grid point mapping program. The program can also output an optional listing of the latitude, longitude, nadir angle, and experimental value of the individual data measurements processed during the preparation of the grid point map.

Documentation publications and complete program listings, as well as operating instructions and procedures for the original programs, may be obtained from the Laboratory for Atmospheric and Biological Science, GSFC.

4.2 Modifications

4.2.1 HRIR Program Modifications

Modifications were made to the original Unified Nimbus HRIR Mercator Map Program to accomplish the following:

- a. Extract and map HRIR data points where the recorded temperature is greater than or equal to some preset threshold value. If the threshold value is set high enough, one may be reasonably sure that the remaining data is cloud free. The penalty paid in such a case however, is that a large percentage of usable cloud free data may also be discarded along with the contaminated points.
- b. Convert temperature values in degrees Kelvin to single digit alphanumeric codes for off-line printing or card punching. The punched card data obtained using this optional modification may then be processed through the Digital Color Printer developed by Allied Research in a separate in-house study. An example of the output of the color printer may be seen in Figure 6-1. A detailed discussion of the Digital Color Printer is given in Section 6.3.2.1.
- c. Permit the composite mapping of multiple passes. This option may be used to construct time averages, or in situations of partial cloudiness when not enough clear-sky data is available on a single pass to permit meaningful analyses. Using a population map, data is averaged in those areas where there is clear-sky overlap from pass to pass.

4.2.2 MRIR Program Modifications

Modifications were made to the original Unified Nimbus MRIR Mercator Map Program to accomplish the following:

- a. Extract and map MRIR data points from Channels 1, 2, 3, or 4 when the corresponding Channel 5 reflectance value (albedo format) is less than some pre-selected threshold. Analogous to the HRIR case above, too low a setting of the Channel 5 threshold guarantees cloud-free analyses, but loses much of the valid data. Of course, this option is applicable only to the daytime passes when Channel 5 albedo data is available.
- b. Extract and map MRIR data points from any channel when the corresponding Channel 1, 2, 3 or 4 value is greater than some pre-selected threshold. This option was used primarily for nighttime cloud discrimination by mapping Channel 2 (temperature) data when the corresponding Channel 1 (water vapor) value exceeded some threshold. Details on this technique and selection of the threshold may be found in Section 5.2.2.
- c. Convert temperature data to alphanumeric codes as in option (b) of the HRIR data above.
- d. Permit the composite mapping of multiple passes as in option (c) of the HRIR data above.

4.3 Program Structure and Operation

4.3.1 HRIR Program

4.3.1.1 Structure

The program deck is available as a source deck consisting of a main program and 18 subroutines. The main program and five subroutines are written in FORTRAN II. The remaining subroutines are written in the FAP machine language. An object deck is also available. Execution is under the control of the IBM 7094 FORTRAN II monitor.

A general flow chart for the main program is given in Figure 4-1. This program is the control unit linking together the subroutines and input variables necessary to map the radiation data.

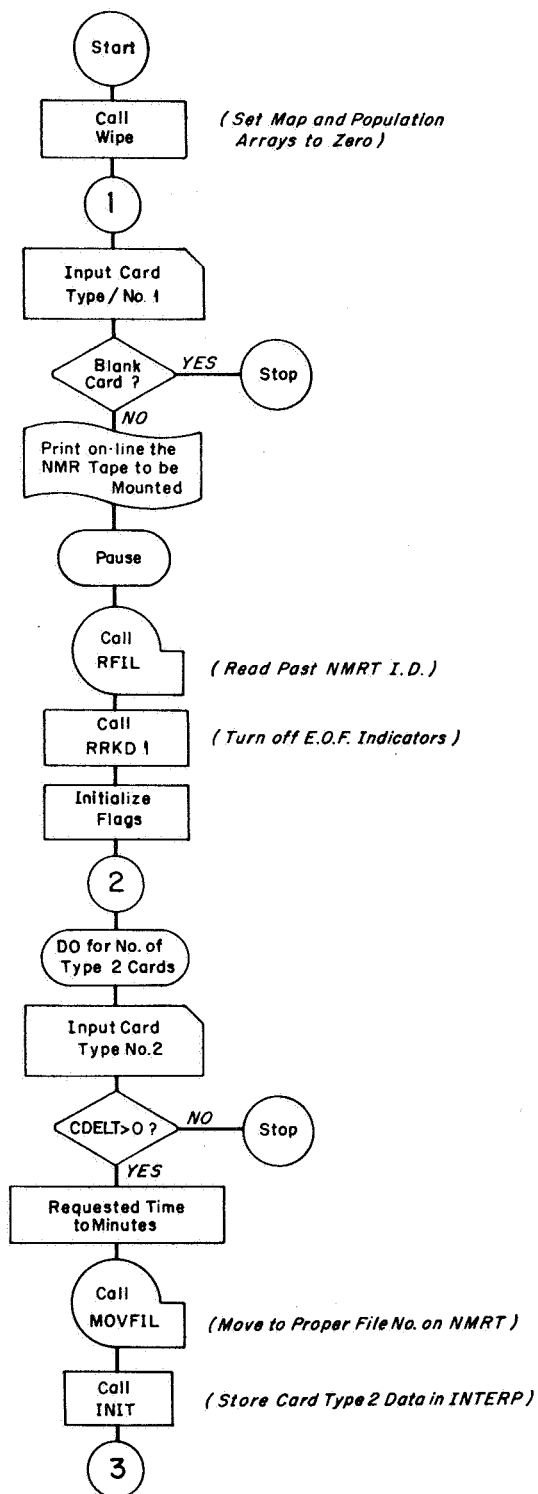

Figure 4-1 Main Program Flow Chart

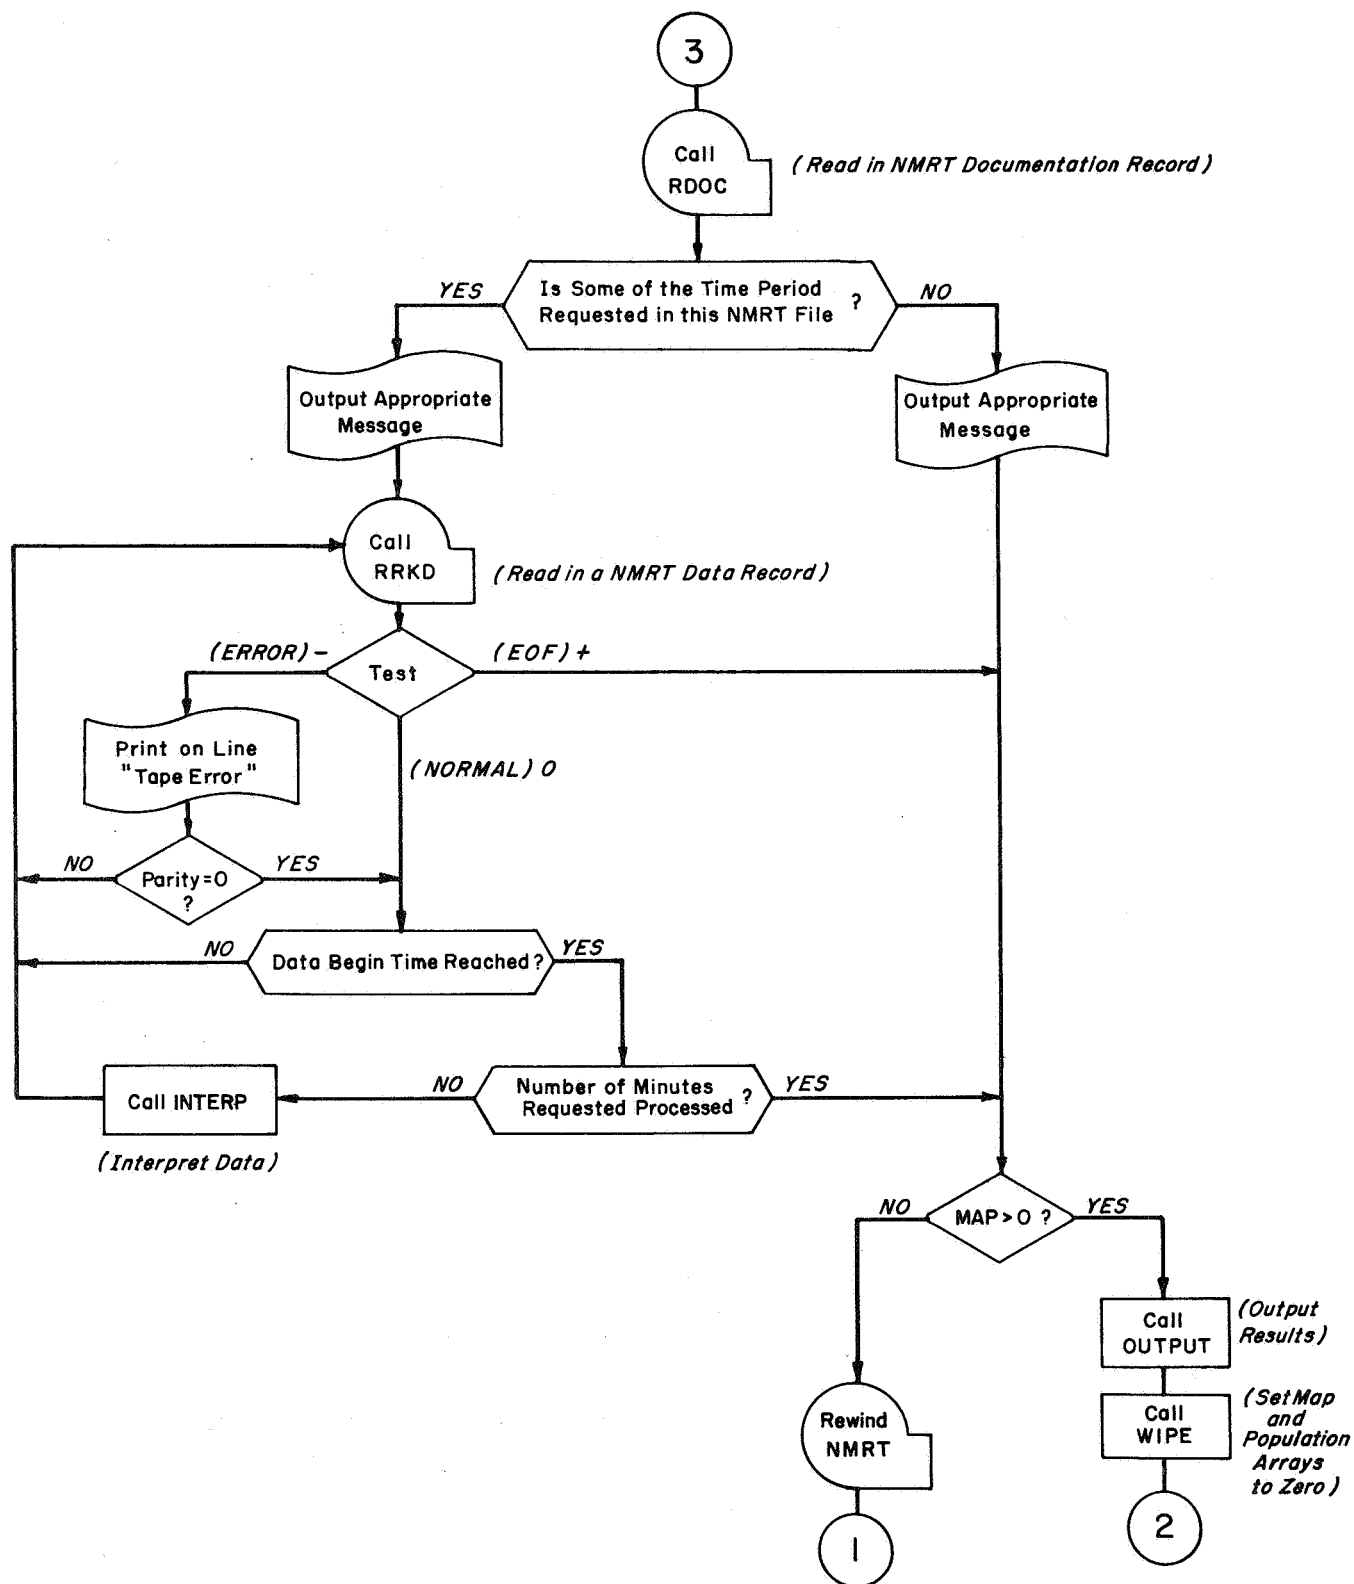

Figure 4-1 (Cont'd) Main Program Flow Chart

4.3.1.2 Magnetic Tape Mountings

The selected NMRT's are mounted on Tape Unit B-9 at 800 BPI. A blank tape is mounted on Tape Unit A-8 for card output. A scratch tape is mounted on Tape Unit A-3 for optional output information upon completion of main program.

4.3.1.3 Control Cards

There are two types of control cards used in this program. The Type 1 card contains the tape number of the NMRT and the number of Type 2 cards to follow. The format for the Type 1 card is given in Table 4-1. A Type 2 card is required for each map or each time segment within the request. A terminal blank card is placed at the end of the program deck, followed by an End of File (EOF) card. The format for the Type 2 card is given in Table 4-2.

Table 4-1
Type 1 Card Format (HRIR and MRIR)

Columns	Format	Symbol	Definition
1-5	15	JTAPE	Tape number of the NMRT to be mounted on B9.
6-7	12	JCARDS	Number of Type 2 cards to follow.

The card deck setup for mapping one pass or compositing more than one pass is shown in Figure 4-2.

4.3.1.4 Restrictions

- a. The number of horizontal mesh intervals (DNBR) for any map should not exceed 77.
- b. The number of rows created for any scaled mercator projection is a function of the Northern and Southernmost limits of a map, and this number must be less than 104. Special tables exist for checking the row count in advance.
- c. When compositing orbits, input parameters CONI, CATN, CATS, SESH, DNBR, CUTOFW, CUTOFC on each Type 2 card should always be identical.

Table 4-2

Type 2 Card Format (HRIR)

Columns	Format	Symbol	Definition
1-3	F3.0	CDAY	Day of year of starting point of time interval to be mapped
4-5	F2.0	CHOUR	Hour of starting point of time interval to be mapped
6-7	F2.0	CMIN	Minute of starting point of time interval to be mapped
8-11	F4.0	CDELTA	Time interval to be mapped in minutes
12-13	F2.0	CNADR	Value of nadir angle above which data is not considered
14-17	F4.0	CPASS	Pass number
18-20	F3.0	CONI	Easternmost longitude (measured from 0° to 360° westward)
21-23	F3.0	CATN	Northernmost latitude to be displayed in map; negative if in southern hemisphere.
24-26	F3.0	CATS	Southernmost latitude to be displayed in map; negative if in southern hemisphere
27-31	F5.3	SESH	Number of degrees of longitude per horizontal map interval. (Determines map scale)
32-34	F3.0	DNBR	Number of grid lines to form map
35			Blank
36	F1.0	PARITY	Non-zero value in this column causes a data record input with a parity error to be skipped in processing
37	F1.0	WRDAT	Non-zero value in this column causes information on each data point mapped to be written on A3 (optional listing)
38-39	I2	IFITGO	Number of data file of NMRT in which processing is to be done
40			Blank
41-42	I2	MAP	0-Composites maps; 1-Output maps in card form only; 2-Output maps in both card form and regular printed form
43-48			Blank
49-51	F3.0	CUTOFW	Used for card output. Any temperature greater than or equal to CUTOFW will be represented as a 9 punch on a card
52-54	F3.0	CUTOFC	Any temperature less than CUTOFC is rejected during map construction
55	A1	INK	Any printer character desired to represent no data on a card (usually left blank)

Figure 4-2 MRIR-HRIR Data Setup

4.3.2 MRIR Program

4.3.2.1 Structure

The program deck is available as a source deck consisting of a main program and 19 subroutines. The main program and six subroutines are written in FORTRAN II. The remaining subroutines are written in FAP. An object deck is also available. Execution is under the control of the IBM 7094 FORTRAN II monitor.

The general flow chart for the main program is identical to that presented for the HRIR program (Refer to Fig. 4-1).

4.3.2.2 Magnetic Tape Mountings

Identical with the HRIR case; refer to Section 4.3.1.2.

4.3.2.3 Control Cards

As before, there are two types of control cards used in this program. Card Type 1 remains unchanged. Refer to Table 4-1. Columns 1 through 39 of card Type 2 also remain unchanged. The format for the MRIR Type 2 cards is given in Table 4-3.

See Figure 4-2 for card deck setups.

4.3.2.4 Restrictions

- a. Same as Section 4.3.1.4 (a) above.
- b. Same as Section 4.3.1.4 (b) above.
- c. When compositing orbits, input parameters CONI, CATN, CATS, SESH, DNBR, KCHAN, DISCRM, CUTOFW, CUTOFC, and IFV on each Type 2 card should always be identical.

Table 4-3
Type 2 Card Format (MRIR)

Columns	Format	Symbol	Definition
1-3	F3.0	CDAY	Day of year of starting point of time interval to be mapped
4-5	F2.0	CHOUR	Hour of starting point of time interval to be mapped
6-7	F2.0	CMIN	Minute of starting point of time interval to be mapped
8-11	F4.0	CDELTA	Time interval to be mapped in minutes
12-13	F2.0	CNADR	Value of nadir angle above which data is not considered
14-17	F4.0	CPASS	Pass number
18-20	F3.0	CONI	Easternmost longitude (measured from 0° to 360° westward)
21-23	F3.0	CATN	Northernmost latitude to be displayed in map; negative if in southern hemisphere
24-26	F3.0	CATS	Southernmost latitude to be displayed in map; negative if in southern hemisphere
27-31	F5.3	SESH	Number of degrees of longitude per horizontal map interval (Determines map scale)
32-34	F3.0	DNBR	Number of grid lines to form map
35			Blank
36	F1.0	PARITY	Non-zero value in this column causes a data record input with a parity error to be skipped in processing
37	F1.0	WRDAT	Non-zero value in this column causes information on each data point mapped to be written on A3 (optional listing)
38-39	I2	IFITGO	Number of data file of NMRT in which processing is to be done
40	I1	KCHAN	MRIR channel number to be mapped
41-42	I2	MAP	0-Composites maps; 1-Output maps in card form only; 2-Output maps in both card form and regular printer form
43-48	F6.2	WSTAR	Channel 5 \bar{W} * reflectance value
49	I1	IFV	Number of discriminating channel
50-55	F6.3	DISCRM	Threshold value
56-57	I2	JSZAL	Solar zenith angle limitation for Channel 5 reflectance
58-60	F3.0	CUTOFW	Used for card output. Any temperature greater than or equal to CUTOFW will be represented as a 9 punch on a card
61-63	F3.0	CUTOFC	Used for card output. Any temperature equal to or less than CUTOFC will be represented as a 12 punch (+) on a card
64	A1	INK	Any printer character desired to represent no data on a card (usually left blank)

4.4 Subroutines

4.4.1 HRIR Subroutines

This section lists the HRIR subroutines and gives a brief summary of their purpose:

<u>Subroutine</u>	<u>Purpose</u>
WIPE	Called by main program to set NGATE flag to 1 for entry to SST for initialization of map arrays
MOVFIL	Called by main program to locate proper file on NMRT
RDOC	Called by main program to read NMRT documentation record
RFIL	Called by main program to read past NMRT I.D. file
INIT	Called by main program to store card Type 2 data for use by INTERP. Calculates upper and lower limits of map
INTERP	Called by main program to unpack data contained in an NMRT. Calls upon other subroutines to calculate nadir angle, latitude, longitude and map coordinates. Rejects data on basis of discriminant as they are called up
COMPA	Called by INTERP to calculate nadir angle of data point
TINI	Called by INTERP to calculate latitude and longitude of data point
MGRID	Called by INIT and INTERP to calculate number of map rows required and map coordinates
OUTPUT	Called by main program to set NGATE flag for requested options for entry to SST
SST	Called by INTERP, WIPE and OUTPUT to accomplish one of five tasks as a function of NGATE setting: (1) initialize map arrays (2) compile map data (3) calculate average (4) output maps in printed format (5) output maps in card format
IBLK	Called by SST to acquire no-data card code
HEAD	Called by INTERP to write heading line to identify data listed by WRITE
WRITE	Called by INTERP to write accepted data values

RRKD	Called by main program to input next data record
RRDK1	Called by main program to initialize redundancy and EOF indicators to off condition
FXFLO	Called by various subroutines. Fixed to floating point
FLOFX	Called by various subroutines. Floating to fixed point

4.4.2 MRIR Subroutines

MRIR subroutines MOVFIL, RFIL, TIN1, MGRID, SST, RRKD, RRKD1, COMPA, FXFLO, and FLOFX are identical with the corresponding HRIR subroutines. The remaining eight HRIR subroutines have equivalent like-named counterparts in the MRIR programs, but with some changes due to basic data format differences (see Appendix A).

The MRIR program has one additional subroutine:

<u>Subroutine</u>	<u>Purpose</u>
N2C5R	Called by INTERP to calculate Channel 5 reflectance

5. CLOUD DISCRIMINATION

Since the early TIROS studies the presence of cloudiness has remained the primary deterrent to obtaining accurate SST maps of sufficiently wide coverage. While nothing can be done to remove the effects of cloudiness, considerable effort has been placed into the task of at least removing cloud contaminated data points from the temperature analyses.

5.1 Daytime Cloud Discrimination

5.1.1 HRIR Daytime Cloud Discrimination

The 3.5 to 4.1 μm spectral region of the HRIR sensor extends far enough into the solar radiation spectrum so that daytime HRIR measurements are strongly influenced by reflected solar radiation. Clouds may appear either light or dark depending upon some combination of temperature and brightness, and are nearly impossible to accurately distinguish. As a result, daytime HRIR cases were not used in this study although evidence of the north wall of the Gulf Stream may be seen in some of the passes. The absolute temperature values recorded however, even in the clear areas, cannot be relied upon due to the solar reflectance problem.

5.1.2 MRIR Daytime Cloud Discrimination

Past studies have shown that, in the absence of sunglint, the reflectance, or albedo, of the sea surface is extremely low compared to cloud reflectance. By setting an appropriate albedo threshold value, cloud contaminated data points can be effectively eliminated (Conover, 1965). Analysis of the Nimbus II daytime MRIR data has resulted in the choice of a 15% albedo threshold value as the cut-off between clear and cloudy areas. This particular reflectance value corresponds most closely with abrupt changes in Channel 2 temperature as the sensor enters or leaves a cloudy area.

One difficulty, however, is that the presence of thin cirrus clouds is often not readily apparent in the reflectance channel data. Because of their cold black body equivalent temperatures though, these clouds do exert a marked influence on the Channel 1 data. Channel 1, which operates in the 6.4-6.9 μm water vapor absorption band, records the ambient temperature of the atmospheric moisture. As

a result, an investigation was conducted to determine the feasibility of jointly using the Channel 5 reflectance, and Channel 1 water vapor data (combine options (a) and (b) of Section 4.2.2 above) to delineate cloud contaminated areas.

The investigation was based on the joint analysis of daytime satellite data (MRIR) and ground based cloud observations extracted from WBAN 10 forms. Since cloud reports are readily available only over land areas, case studies were confined to the eastern coast of the U.S. The results of these studies showed that for the safest and most complete elimination of cloud contamination from the Nimbus daytime data, it is necessary to use a combination of the 15 % albedo threshold and a 237°K water vapor threshold (clear, for Channel 1 temperature greater than 237°K). The ability to distinguish cloudiness using Channel 1 data has immediate application to the problem of nighttime cloud discrimination when albedo data is not available. Details of similar case studies run for the Gulf Stream region, and the choice of the 237°K Channel 1 threshold value, are provided below in the discussion of MRIR nighttime cloud discrimination.

5.2 Nighttime Cloud Discrimination

5.2.1 HRIR Nighttime Cloud Discrimination

The Nimbus II HRIR radiometer operated in a single spectral region so that the only readily available means for cloud discrimination were the temperature data themselves. The choice of a threshold value in this case is relatively arbitrary, although 280°K is one value commonly used. This value assures that most of the truly cloud-free data will be included, while the amount of cloud contamination is kept relatively small. Fog, low warm clouds, and high thin cirrus are cloud types most commonly missed by this technique.

The possibility of developing computer programs to eliminate cloud from the nighttime HRIR data using the MRIR water vapor data was considered. Because of the relatively short lifetime of the MRIR sensor (74 days, 15 May to 28 July 1966) relative to the HRIR (6 months) and the probable complexity of such a program, it was not felt that such an effort would be justified. To demonstrate that such an approach could be taken, however, a few cases were run where the melding of the MRIR and HRIR data was done by hand. An example of one such analysis may be seen in Figure 5-1

These are the nighttime HRIR data from Pass 380 of Nimbus II. Two types of cloud discrimination are used: HRIR temperature below 282°K , and MRIR Channel 1 data below 237°K . The area is off the southern coast of South Africa. In this region the warm Agulhas Stream flows south along the eastern coast of Africa to about 40°S . There, it encounters the cool Southern Hemisphere West Wind Drift at Cape Agulhas. Starting at Cape Agulhas, the cold Benguela Current moves northward along the western coast of Africa. In the cloud-free areas one may clearly see evidence of both the Agulhas and Benguela currents. The fine structure in the temperature patterns is typical of HRIR SST maps. There is at present considerable controversy as to the "reality" of these detailed patterns. Unless some direct connection to sensor noise is discovered, it is a question which may never be resolved. In fact there may be no solution. Due to the nature of remote IR measurements (i.e. sensing only the top few tenths of millimeters of the water surface), these patterns may be "real" only to IR instruments and would never be observed in the conventional ship data.

5.2.2 MRIR Nighttime Cloud Discrimination

In seeking a Channel 1, water vapor, threshold value for use in nighttime cloud discrimination, two types of analyses were performed. One was a simple matching of the Channel 1 patterns with the reflective patterns of Channel 5. The other was a statistical analysis of the significance of assumed Channel 1 clear area criteria.

5.2.2.1 Channel 1/Channel 5 Matching

Consecutive daytime MRIR passes for approximately one week were run for the Gulf Stream region. Cloud free areas, as indicated by using various Channel 1 thresholds, were compared with those obtained using the Channel 5, 15% albedo cut-off. For each water vapor threshold, two numbers were calculated: the false alarm rate, i.e. the probability that a point indicated to be cloud was in fact clear, and the failure rate, i.e., the probability that a point indicated to be clear was in fact cloud. The results for a typical pass are shown in Figure 5-2. These data were derived from Pass 511 on 22 June 1966. It will be noted that for thresholds less than 239°K , the false alarm rate approaches 50%. As expected, the "false alarm" rate generally exceeds the failure rate. This is because the Channel 5 albedo

Figure 5-2 Channel 1 False Alarm - Failure Rate (Nimbus II, Pass 511)

discrimination technique, as mentioned above, tends to miss certain cloud forms such as high thin cirrus. Analysis of several cases such as that shown in Figure 5-2 led to a choice of 237°K as the Channel 1 water vapor, clear-cloudy threshold. As usual, any such choice involves a trade-off between data quality and data quantity. In our studies quantity was often sacrificed to obtain higher quality, more cloud-free analyses.

Figure 5-3 shows the analyzed Channels 1, 2 and 5 data for orbit 470. Only the following isolines are shown:

Channel 1: 235°K
Channel 2: 280°K and 290°K
Channel 5: 20% albedo

From the figure, the following points may be made:

a. Areas having a Channel 1 temperature less than or equal to 235°K , correspond very well with areas having albedos less than or equal to 20%. An exception is the band of cool Channel 1 temperatures between 10° and 20° North.

b. Within this cool band, however, it is interesting to note that there are areas where the Channel 2 temperatures are less than 280°K (high thin cirrus?).

c. On the whole, Channel 2 temperatures less than 280°K fall within the areas where the Channel 1 temperature is less than 235°K , and the Channel 5 albedo exceeds 20%.

As would be expected, the downward revision of a Channel 5 threshold can be best matched by a corresponding increase in the Channel 1 threshold. Thus, the ultimate choice of a 237°K water vapor channel threshold is consistent with a slightly lower (15%) albedo threshold than the one used in this example.

5.2.2.2 Statistical Approach

A study was made of the statistical significance of several Channel 1 thresholds, T_t , used in conjunction with a Channel 5 albedo threshold, R_t , of 12%. The technique used was that of computing chi-square values based upon contingency tables. Each of the data points in a chosen area was counted as belonging to one of the four following categories:

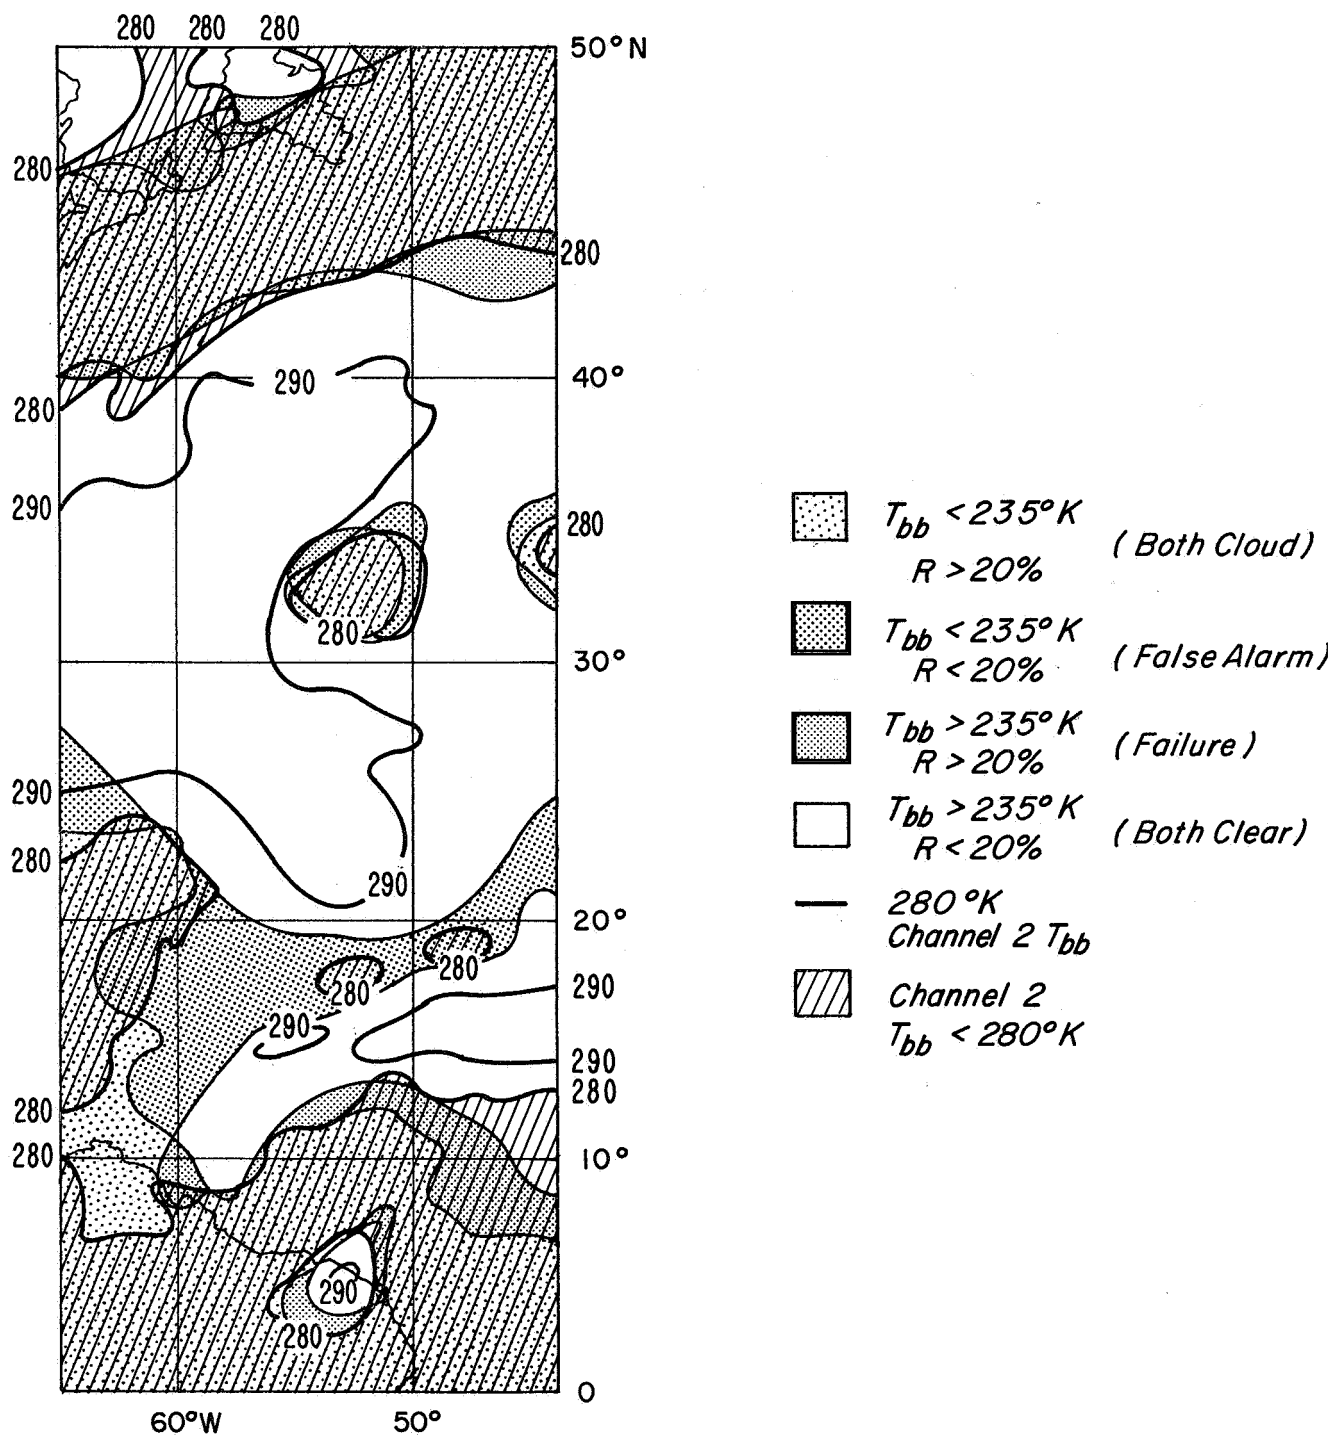

Figure 5-3 Analyzed Channels 1, 2 and 5 Data (Nimbus II, Pass 470)

- I : $R \leq 12\%$, $T \geq T_t$: both indicate clear
 II : $R \leq 12\%$, $T < T_t$: false alarm
 III : $R > 12\%$, $T \geq T_t$: failure
 IV : $R > 12\%$, $T < T_t$: both indicate cloud

where R is the Channel 5 reflectance, and T is the Channel 1 temperature.

An example of these calculations for two widely separated Channel 1 thresholds is seen in Table 5-1 below.

Table 5-1
 Cloud Discrimination Contingency Tables

$T_t \backslash R_t$	$\leq 12\%$	$> 12\%$
$\geq 235^\circ\text{K}$	1143	563
$< 235^\circ\text{K}$	227	315

$$\chi^2 = 109.0$$

$T_t \backslash R_t$	$\leq 12\%$	$> 12\%$
$\geq 241^\circ\text{K}$	386	128
$< 241^\circ\text{K}$	984	750

$$\chi^2 = 56.1$$

These data represent a composite of several MRIR passes over the same geographic area. As can be seen, at the lower Channel 1 threshold of 235°K , the failure rate exceeds the false alarm rate, while with the threshold at 241°K , the reverse is true. It should be noted that the calculated chi-squares are pessimistic insofar as the "false alarm" rate is artificially high due to the inability of the albedo channel to discern certain cloud forms.

A graph of the computed chi-square values for seven Channel 1 thresholds is presented in Figure 5-4. This parameter is seen to peak at a Channel 1 threshold of 237°K , although the curve is relatively flat from 235° to 237°K . In each case, the probability of a value of χ^2 being at least as great as those shown here is much less than 1%, so that the degree of association between the Channel 1 and Channel 5 thresholds is quite significant. As can be seen, the justification for rejection of the null hypothesis decreases sharply for Channel 1 temperatures greater than 239°K .

Figure 5-4 Computed Chi-Square Values

5.3 Summary

As has been shown, a combination of visible, IR window, and water vapor absorption data is best suited to the detection of cloud contaminated data points. In the nighttime cases only the temperature and water vapor data are available. Thin cirrus clouds may be missed by the visible channel, but are usually detected in the water vapor band. While tentative thresholds of 15% albedo, 280°K , and 237°K have been established for the visual, temperature, and water vapor channels respectively, no unique fail-safe set of thresholds are available. The use of manned spacecraft observations to further resolve clear-cloudy radiation differences, and to examine such problem areas as small (less than the sensor resolution) scattered cloudiness is discussed in Section 8.

6. RECOMMENDATIONS ON OPTIMUM DATA SOURCES, PROCESSING AND ANALYSIS

6.1 Data Sources

As outlined earlier in this report (Section 1.3), the most ideal satellite system for the operational measurement of cloud-free sea surface temperature data would be a near-polar orbiting sun synchronous vehicle with high resolution cross-track scanning in several spectral regions. The multiple spectral region feature if properly calibrated would permit real time flagging of cloud contaminated data, and hence the immediate mapping of clear sky temperature data. It should be noted that TIROS-M, scheduled to be launched during the second quarter of 1969, closely approximates such a system. It will be in a sun synchronous orbit and carry a two channel (.52 to .73 μ m, visible and 10.5 to 12.5 μ m, infrared), high resolution (4 n.mi. at subpoint), scanning radiometer. Real-time processing of the radiation data with a digital tape output is being planned by the National Environmental Satellite Center (NESC).

In the absence of real time measurements of visible radiation data to complement the infrared information, an alternate source of cloud data must be sought. Since October 1966, NESC has mapped satellite visible imagery on a daily global basis for a variety of users (Bristor, 1968). Earth locator information is used to determine the latitude and longitude of each digital brightness sample. These locations are replotted as a digital map in a standard polar stereographic or other type projection for easy comparison with other environmental data. A fine mesh (4096x4096) map array is reserved on computer disks for each polar hemisphere. Since January 1967, archival hemispheric tapes have been prepared with mesoscale (512x512) arrays. A point-to-point message format tape is available for relay and further treatment by computer.

The digitized cloud maps described above could serve as a substitute for other, more direct, cloud discrimination data if the latter are not available. These maps would, of course, be usable only for the daytime data. One problem which would be encountered is that the digitized cloud maps are not, in general, valid for the precise time of the infrared measurements. Possible solutions to this problem include the artificial enlargement of the indicated cloud areas as a function of the

magnitude of the time discrepancy, or even advecting the clear-cloudy information in time. Insofar as this latter approach requires a knowledge of the existing wind field, and neglects such phenomena as cloud dissipation and generation, its use is probably not feasible at the present time.

6.2 Data Processing

6.2.1 Use of Temperature Gradients

Within the present state-of-the-art, it is not possible to accurately account for the absolute effects of atmospheric attenuation on a real-time basis. (Present Nimbus data yields accuracies of ± 1 to 2°K only if corrections for atmospheric attenuation of ± 1 to 5°K are applied). To do so would require a detailed knowledge of the temperature and humidity structure of the intervening atmosphere. Ways to accomplish this are currently being investigated (Bandein, 1968), but are not as yet available. Possible approaches include the use of a Temperature Humidity Infrared Radiometer (THIR) and a Filter Wedge Spectrometer (FWS), both of which are being developed to fly on Nimbus D in the first quarter of 1970.

Until it is possible to automatically include atmospheric attenuation effects, the operational use of satellite derived sea surface temperature information must be restricted to the use of temperature gradients only. These gradient data must then be combined with the absolute temperature values as recorded by conventional shipboard measurements.

In combining the satellite gradient data and ship data, FNWF currently produces a daily computer drawn SST map for the Northern Hemisphere utilizing a data base of 84 hours of conventional surface ship data. In view of the vast time and distance scale advantages of satellite radiation data, real-time melding of cloud-free, satellite derived, sea surface temperature gradient data with the conventional shipboard observations should be considered. Assuming the existence of a multi-spectral, high resolution radiometer, the cloud discrimination techniques discussed in Section 5 above would be immediately applicable to such a program. A flexible, three dimensional temperature surface, is, in effect, mathematically fit to the array of surface measurements which act as a forcing function on the satellite data. General mathematical techniques to meld gradient and absolute data are available and are adaptable to the CDC 6500 computers used by the Fleet Numerical Weather Facility (Danard, 1967). Of course, the use of gradient data does not affect the requirement for recognition of cloud contaminated data.

6.2.2 Atmospheric Attenuation

While it is not yet possible to remove entirely the effects of atmospheric attenuation, some corrections can be made for its variation, both with nadir angle and geographic location. Correcting for the variation with nadir angle would be a relatively simple task. The magnitude of this effect has already been evaluated in certain spectral regions for standard atmospheres (Wark, 1962). Current programs avoid the worst of the nadir angle problem by rejecting data acquired above some specified nadir threshold (see input CNADR on Card Type 2, Tables 4-2 and 4-3).

Correcting for the spatial variation of attenuation called for in large scale operational applications would be a considerably more difficult task. If this is not done, however, the varying attenuation patterns caused by changes in air mass will introduce false temperature gradients into the analyses. Possible sources of humidity data might include FNWF's 12 hourly analysis of the atmospheric mass structure, or some variation of the Nimbus II Channel 1 water vapor data. The possibility of using data from a water vapor absorption band has already been investigated (Fritz, 1967 and Bandeen, 1968).

6.2.3 Data Compositing

Insofar as the ship data used by FNWF in their daily SST maps must be accumulated over 3-1/2 days (to insure enough data for meaningful analyses,), it may be desirable to increase the effective coverage of the satellite data by compositing it over a number of passes. Again, the techniques for doing so have been developed. Just how much coverage can eventually be obtained as a function of the compositing interval is highly dependent upon the particular geographic region in question. Additionally, the variation in time of the desired surface temperature patterns places limits upon the duration of compositing time which can be tolerated. Compositing over too long a period may average out or obscure the patterns intended for study. Considerations such as these are particularly useful in planning research programs, or in evaluating the potential usefulness of satellite data for particular applications. A more detailed discussion of such considerations with particular emphasis on the Gulf Stream region will be presented in Section 7.1.

6.3 Data Analysis

6.3.1 Operational Use

The approach to the problem of data analysis depends to a great extent upon the use to which the data will eventually be put. Certainly for operational applications, computer drawn analyses represent the only feasible solution. In case of the FNWF daily SST maps of the Northern Hemisphere, the requirement for rapid dissemination and transmission of these data necessitates a simple format consisting of computer drawn isolines of uniform temperature. Computer generated color presentations are currently possible, but require elaborate and expensive techniques and equipment, and cannot be easily transmitted to other locations.

6.3.2 Research Use

6.3.2.1 Digital Color Printer

For research applications, the tedious and time-consuming hand analysis of the resultant temperature maps continues to be the most prevalent approach. Even the interpretation of computer-drawn analyses can be extremely difficult, often requiring hand coloring of the temperature patterns. In an attempt to by-pass this problem, particularly in the development of the Gulf Stream time history to be discussed in Section 7.2 a simple photographic device developed under a separate in-house study by Allied Research was employed.

The Digital Color Printer may be used to produce color coded analyses of any digital array. The number of possible color selections is limited chiefly by the ability of the human eye to distinguish between them. In its present format, 12 colors are available (one for each row of a standard punched computer card), although by going to a system of mixing colors in a three primary color arrangement, 125 separate hues may be obtained. In the present system the numerical values of any digital array must first be converted to a single digit, alphanumeric code for output in a punched card format. (As seen in Section 4, this option is now included in both the modified MRIR, and HRIR programs.) The punched cards are

then placed on a color filter platen and their image is effectively swept past a slit aperture producing a row of color coded spots corresponding to a row of numbers of the original digital array. The color strips of the filter platen may be easily interchanged or replaced so that particular features of the analysis may be emphasized without re-running the program.

An example of the output of the Digital Color Printer may be seen in Figure 6-1. These HRIR data are recorded over the Gulf Stream area at local midnight on 28 August 1966 during pass 1396 of Nimbus II. The scale of the original digitized data was 1:1 million, so that the width of each of the colored squares seen in the Figure is about 7.5 miles. Each of the nine colors represents a 2 degree Kelvin temperature increment ranging from 300°K at the red end to 283°K and cooler in the blue. On the left side of the map, the relatively cool land areas of the east coast, including Cape Hatteras and the DelMarVa Peninsula stand out against the warmer waters of the Atlantic Ocean and the Chesapeake Bay and the Delaware Bay. The north wall of the Gulf Stream is clearly seen in the central portion of the picture, outlining a major meander. The cooler temperatures seen in the southeast portion of the analysis are due to partial cloudiness.

Figure 6-2 shows a hand drawn analysis of the same data. While the location of the Gulf Stream can be inferred, its position is not nearly as obvious as it was in Figure 6-1. It is clear that the use of the Digital Color Printer, or similar devices can save a considerable amount of time and effort which would otherwise have been spent in analyzing and interpreting the traditional grid-print maps.

6.3.2.2 Single-Digit Analyses

In working with the Digital Color Printer it was found that a simple print-out of the punched card data resulted in a temperature array which was much easier to analyze than the standard grid-print map. The improvement of course, is due to the ability of the human eye to discern patterns in a field of single-digit alphanumeric symbols. Objections have been raised that the extra step required in such a format, to mentally convert from symbols to temperature values, negates the analysis advantages. We feel, however, that if a sufficiently familiar set of ordered symbols, such as the english alphabet, is used, the advantages of a shorter analysis time will far exceed the disadvantage of converting from symbols to temperatures.

One possible application would be the "full resolution" mapping of the HRIR data where every digitized point in a swath is output in alphanumeric form. A special symbol could be reserved for output at even 5° latitude-longitude intervals. Connecting these special symbols by straight lines would result in a gridded, full resolution HRIR map on a single piece of paper of manageable size. The initial work has already begun at Allied to develop such a full resolution program.

7. MEASUREMENT OF SEA SURFACE TEMPERATURE PATTERNS AND THEIR SYNOPTIC CHANGES

7.1 Remote Measurement of a Time-Varying Phenomenon

A brief glance at any full-disk earth picture reveals that the primary problem in developing a time history of some changing surface feature is the cloud cover. There is a tendency for those oceanographic areas which exhibit the greatest synoptic change, such as the Gulf Stream or any major current, to have frequent and persistent fronts and cloud cover. It is extremely rare that such a large scale feature can be viewed under completely cloud free conditions. These considerations led to a number of questions. How often is it really necessary to view a given area under cloud-free conditions? Would it be sufficient to view it every other day, or every third day, or once a week? If an area is partly cloudy on consecutive days, is it possible to generate meaningful temperature pattern analyses by making composite maps? For a region with varying surface features, what is the probability of obtaining a workable amount of coverage before the patterns change? Is it even possible, except under unusual meteorological circumstances?

The answers to these questions depend to a great extent upon both the nature of the body of water being studied, and upon the climatological characteristics of the intervening atmosphere. As an example of the remote measurement of changing sea surface temperature patterns, the behavior and structure of the Gulf Stream will be considered in Section 7.2. The following paragraphs present a statistical approach to the cloud cover problem. In presenting examples of the generation and application of the cloud statistics, the Gulf Stream region is emphasized.

7.1.1 World-Wide Cloud Data Bank

In a separate study, Allied Research has prepared probability distributions of world-wide cloud cover for use in the simulation of earth-oriented observations from space (Sherr, 1968). The practical use of cloud statistics in computer simulation routines dictates the subdivision of the earth into nominally homogeneous cloud climatic regions. The number of such regions is arbitrarily set by consideration of the data volume that must be handled by the computer and by the amount of suitable

data available. Figure 7-1 presents the selection of 29 cloud regimes derived from standard climatology, general cloud summaries, conventional and satellite observations, and cloud data from selected stations. Note that the Gulf Stream area is included primarily in Regions 13 and 20.

For each of the 29 regions, both unconditional and temporal and spatial conditional cloud cover statistics were derived. The unconditional statistics were derived for eight times of day and for each month of the year. Because of insufficient data, the conditional statistics received only a seasonal stratification. Five cloud-amount categories were defined:

Category 1	Clear skies
Category 2	1, 2 and 3-tenths cloud cover
Category 3	4 and 5-tenths cloud cover
Category 4	6, 7, 8 and 9-tenths cloud cover
Category 5	Overcast.

Unconditional cloud cover statistics are frequency distributions of fractions of sky covered, expressed in percent frequency. The temporal conditional tables present the probability of cloud amount X occurring at some given point 24 hours after the occurrence of cloud amount Y at the same point. The spatial conditional tables present the probability of cloud amount X occurring at some given time 200 miles distant from the occurrence of cloud amount Y at that same time. Data for these tabulations were derived from 10 to 15 years of weather records from approximately 100 observing stations distributed throughout the world. The three to five years of satellite data were used particularly in the preparation of the spatial conditional tables.

Mathematical procedures are provided to adjust the conditional distributions to other time and distance separations. In the case of the temporal conditionals, special procedures are available to account for diurnal effects as 12 or 36 hour intervals are approached. Techniques are also presented to allow the basic statistics (representing approximately a 30 n.mi. circular area) to be scaled into distributions representing enlarged area sizes. These techniques are required due to the marked change in cloud cover distribution as a function of sampled area size. (The cloud cover over a true point can have but two values - clear and overcast. The cloud cover over the entire earth seems to stay reasonably constant at about 40%. Intermediate sized areas have cloud distributions which pass from the U-shape of small areas to more bell-shaped distributions at rates which depend upon the prevalence of large-scale cloud systems.)

Figure 7-1 Region Location Map for Cloud Cover Data

Tables 7-1 and 7-2 present the conditional and unconditional cloud statistics for Regions 13 and 20 for the months of June and October respectively. Note that from the unconditional tables, cloud categories 4 and 5 are the most probable for both regions for both June and October. As an example of the interpretation of these tables, consider the early evening (1900 local time) data for Region 13 for the month of October. Typically, cloud categories 4 and 5 are most probable, while there is only a 1% probability of clear skies. Looking at the conditional tables, one sees that, given initially overcast skies, the probability that the skies will still be overcast 24 hours later is 39%, and that the probability of overcast conditions 200 miles away is 57%. As might be expected, both of these values exceed the unconditional overcast probability of 36%. Given initially clear skies, the probability of continued clear skies 200 miles away is 61%. Note, however, that the most probable cloud coverage 24 hours later is overcast skies. This sort of anti-persistence is typical of areas with high frontal activity.

7.1.2 Use of Cloud Data Bank

7.1.2.1 Procedures

Simulation of cloud influence on specified sensor systems and mission objectives can be readily performed with considerable sophistication. For purposes of illustration, the overall logic employed for a Monte Carlo simulation of an infrared mission to provide SST maps within a specified cloud region will be described. All distribution tables are first organized as cumulative probabilities in ascending order of cloud cover.

Figure 7-2 is a block diagram of the program. Mission iteration number, NOQ, and pass number, n , are initialized. The first draw is made from the unconditional table for the appropriate region by finding which cloud group probability interval contains the random number, RAN. If the cloud group selected, $C(1)$, is number 1 (clear), a suitable tabulation is made to indicate that complete coverage occurred with one pass, and another mission is initiated. If the cloud group is other than number 1, a photo coverage percentage, B , is assigned and the pass number is incremented by 1. A new cloud cover is drawn from the temporal conditional cloud table, using the row designated by the cloud cover drawn on the previous pass (given), and the column designated by a newly selected RAN. The new cloud cover is then used to calculate the incremented clear sky coverage ΔB .

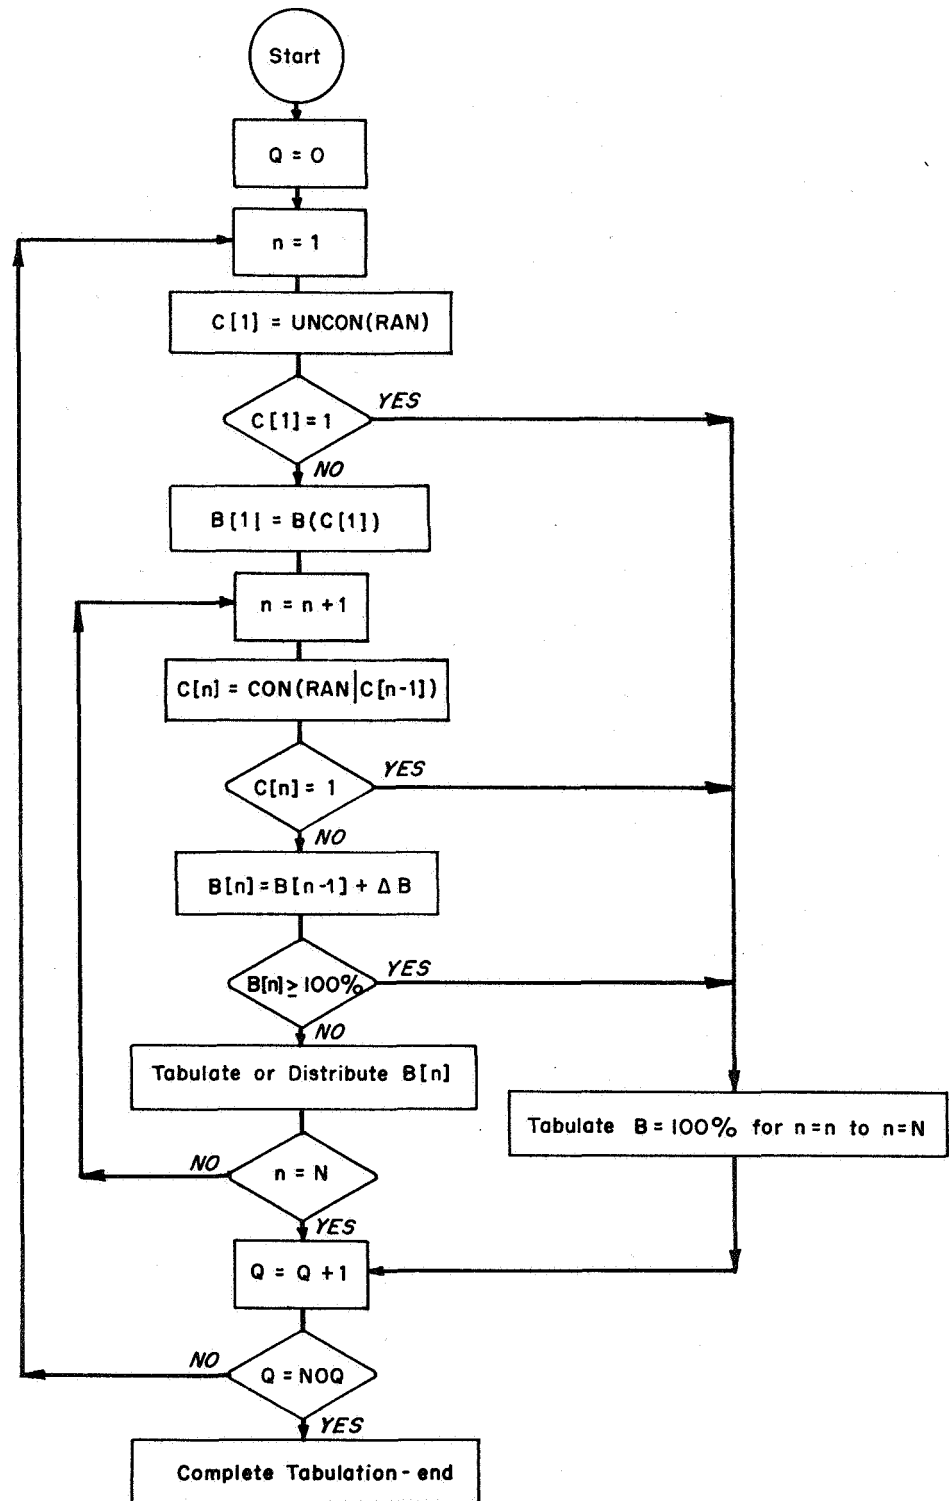

Figure 7-2 Monte Carlo Program to Generate Probability Distribution of Infrared Coverage

The incremental photo coverage is a stochastic function of the existing photo coverage and the new cloud group. The form of the function depends upon the dissection of the cloud, which can be estimated from the original cloud cover distribution. If we assume that the clouds are always randomly scattered over the whole area, the incremental photographic coverage of pass n is given by:

$$\Delta B(n) = [1 - B(n-1)] [1 - A(n)]$$

where $\Delta B(n)$ is the incremental photo coverage added on the n th pass,
 $B(n-1)$ is the photo coverage after $n-1$ passes, and
 $A(n)$ is the cloud amount of the n th pass.

The incremental coverage may add no new information at all, or it may result in total coverage. If it does, the 100% coverage branch is followed. If not, the coverage achieved is recorded as a function of the number of passes. This process is repeated for the N passes allowed in the total mission. The simulation is iterated NOQ times. This simulation approach can provide a quantitative measure of the influence of cloud on specified mission objectives on a regional basis.

7.1.2.2 Application to Gulf Stream

Using the cloud statistics from Tables 7-1 and 7-2, the Monte Carlo Program described above was applied to the Gulf Stream region for the months of June and October. The results are presented in Figures 7-3 and 7-4. Figure 7-3 shows the anticipated cloud coverage for the month of June assuming daily noontime MRIR observations. A simulation of the daily HRIR nighttime observations for the month of October is presented in Figure 7-4. In both cases, a scaled-up area of 300 by 300 n.mi. was employed. Both were computer generated using 300 consecutive mission iterations. The separate curves are labeled by pass number.

The shapes of the curves in Figures 7-3 and 7-4 are generally typical of those developed for other geographic areas. From Figure 7-3, for example, we see that if we are restricted to three-day composites due to changing temperature patterns, we have only a 10% chance of seeing 75% of the area. If a 90% coverage is demanded, there is only a 60% probability of achieving that much coverage, even after eight days. The sharp drop-off of the curves in both figures shows that it may be unrealistic to hold out for very high cloud-free coverage.

Figure 7-3 Statistics for Gulf Stream Region, Noon to Noon Passes, June

Figure 7-4 Statistics for Gulf Stream Region, Midnight to Midnight Passes, October

The increased coverage available in the October nighttime passes (Fig. 7-4) reflects both seasonal and diurnal effects. Now there is a 35% probability of seeing 75% of the area in three passes, and an almost 90% probability after 8 passes of seeing 90% of the area. Thus, it is quite possible that the development of a nighttime cloud discrimination ability will more than double the usable data. Even using the nighttime data, however, it can be seen that certain experiments dealing with short-term, transient oceanographic features will have a very low probability of success. As will be seen in the following section, these statistical results are verified by the MRIR analyses.

7.1.3 MRIR Verification of Cloud Statistics

Twenty consecutive daytime MRIR passes over the Gulf Stream region from 10 to 30 June 1966 were run using the modified programs with a 15% albedo clear-cloudy cut off. The boundaries of the area considered were 34° to 44° North and 58° to 78° West. This region was subdivided into seven smaller areas 5° on a side to approximate the 300×300 n.mi. area for which the computer statistics were generated. The 1:5 million Mercator map scale was used. Only ocean areas were included in the analyses. (The relatively higher reflectance of land areas is often mis-interpreted as cloud.)

The procedure was to form frequency distributions of area coverage using all 20 passes. The passes were considered singly and in groups of five consecutive passes, thereby simulating the unconditional statistics for a single pass, and five-pass coverage respectively. Data for 15 overlapping sets of five consecutive passes each, were generated for each of the seven sub-areas. Figure 7-5 presents a comparison of the unconditional statistics for a 300×300 n.mi. area as generated from the cloud data bank, and as measured in the 20 individual passes. The shift toward lesser cloud amounts reflects clearer than average sky conditions prevailing over the Gulf Stream area for the month of June 1966. This effect is also seen in the measured five-pass coverage shown in Figure 7-6. The measured data present a much more optimistic picture of clear sky probabilities. It should be recalled, however, that the measured June data are representative of only a single year, while those derived from the cloud data bank are based on 10 to 15 years of observations. Considering the differences in the data base, and in the number of independent iterations, it is felt that the MRIR results support the basic statistical procedures.

Figure 7-5 Comparison of Computed and Measured Unconditional Statistics

Figure 7-6 Comparison of Computed and Measured Five-Pass Coverage

The shape of the two curves in Figure 7-6 are quite similar, while the upward displacement of the "measured" curve can be at least partially accounted for by the unusually cloud-free conditions evident in Figure 7-5. It is nevertheless possible, however, that a more extensive measurement program could reveal a pessimistic tendency in the currently used cloud model. For example, in the equation presented for the incremental coverage occurring on the n th pass, $\Delta B(n)$, in Section 7.1.2.1, unless the cloud amount on the n th pass, $A(n)$, is zero, complete coverage will never be achieved. For this reason, it is now felt that straight line extrapolation of the predicted curves beyond 90% coverage may be more realistic. It is nevertheless felt that the current techniques can provide valid information as to the feasibility of a variety of potential remote sensing projects.

7.2 The Gulf Stream Region

7.2.1 Description

Any description of the Gulf Stream region presented here must necessarily be confined to a brief general discussion of its physical characteristics. An excellent review of the whole Gulf Stream problem may be found in the introductory textbook by Von Arx (1962).

The surface water of the Gulf Stream is mainly derived from the southern part of the North Equatorial Current. Water driven by the trades moves slowly across the equatorial North Atlantic, through the Antilles into the Caribbean Sea, and through the Yucatan Channel into the southeastern portion of the Gulf of Mexico before entering the Straits of Florida and the Gulf Stream system.

From Cape Hatteras it extends toward the northeast at a mean bearing of about 070 degrees. To the southeast of this meandering current are the relatively uniform waters of the Sargasso Sea, while to the northwest are the slope waters off the eastern continental shelf. The main current has an effective width of from 25 to 40 n.mi., and a velocity ranging from 45 to 140 n.mi. per day. The meander patterns tend to migrate and amplify downstream, becoming increasingly complex, often breaking off to form warm or cold water eddies. The average wavelength of these meanders is about 200 n.mi., while the mean peak-to-peak height is 70 n.mi. Propagating speed of the meanders themselves seems to range from 4 to 10 n.mi. per day (Naval Oceanographic Office, 1967), although recent evidence suggests that they may at times become quasi-stationary (Wilkerson, 1967). Temperature

gradients of 5 to 10°K per 10 n. mi. exist across the northeastern boundary (north wall) of the stream. The temperature gradients tend to be smaller in the summer and fall when they are masked by intense surface heating of the cold Labrador water.

7.2.2 HRIR Observations

In the 174 day history of HRIR observations, the Gulf Stream was detected on approximately 75 separate occasions. For possible use by other investigators, Table 7-3 presents a listing of these sightings giving the pass number, the date, and a four-level subjective rating as to the usefulness of the data ranging from poor to excellent. Almost 28% of the nighttime sightings occurred during the month of October 1966. Because of this unusually high rate of observation, the October data were chosen for the development of a time history of the Gulf Stream meander movement. Data from 12 passes (11 separate days) with a rating of fair or better were run and analyzed for the period 1 through 31 October. (Passes 1848 and 2128 could not be processed due to problems in the digital NMRT's.)

Figures 7-7 through 7-14 indicate the determined position of the north wall of the Gulf Stream for those days where a sufficient portion of it could be positively identified. A solid line is used to indicate the stream boundary when its location is reasonably certain. Dashed lines are used to bridge areas of cloud contamination. These interpolations were made on the basis of maintaining internal pattern consistency, and occasionally maintaining pattern consistency from pass to pass. When the cloud cover becomes sufficiently wide-spread so that extrapolation of the stream boundary is more or less arbitrary, no boundaries are shown. In all cases, geographic referencing was achieved by aligning the temperature patterns at the left of the analyses with the eastern coastline of the United States.

The first analysis (Fig. 7-7) is that of HRIR pass 1889 on 4 October 1966. Three meanders are apparent beginning off the coast of Cape Hatteras. (There is some evidence that the first two meanders may actually comprise only one meander with some cloud contamination occurring at its northern-most peak.) The third of the meanders is represented in dashed lines, since its exact position could not be determined from this analysis. The location indicated is based upon the position of a large meander observed in the following analysis.

Table 7-3
Nighttime HRIR Gulf Stream Observations

Figure 7-13 Position of the North Wall of the Gulf Stream (Pass 2208)

Figure 7-14 Position of the North Wall of the Gulf Stream (Pass 2222)

Pass 1942, occurring four days later on 8 October is shown next (Fig. 7-8). This time evidence of three major meanders can be clearly seen. The first of these seems to be comprised of two smaller meanders, although cloud contamination may again be at fault. The third meander extends far to the north and may represent the formation of a warm water eddy. From the leading edges of the first major meander in the last two analyses, a barely discernible meander movement of 4 n.mi. per day was inferred. The Digital Color Printer analysis of pass 1942 may be seen in Figure 7-15. The overlay shows the eastern coastline, as well as the stream boundary, and the location of cloud contamination. The individual colors represent 2°K temperature intervals beginning with 297 to 298°K (and higher) at the warm (red) end.

In the analysis of pass 1955 (Fig. 7-9) on the following day, four separate meanders are visible. Again, the last of these may actually represent the formation of a warm water eddy.

The linkage between the fourth apparent meander in the next analysis (Fig. 7-10) three days later and the rest of the stream boundary is unclear due to the presence of cloud contamination. Meander movement between the 8th and the 12th of October was too small to measure accurately. A Digital Color Printer analysis of this pass (1995) is presented in Figure 7-16. The color coding and overlay formats remain the same.

In pass 2022 on 14 October (Fig. 7-11) only the first three meanders are visible. Their position is relatively unchanged from the previous analysis.

On the following day in pass 2035 (Fig. 7-12) there is again evidence of a well developed fourth meander. Comparison of this pass with that of 8 October revealed a difference in speed between individual meanders with higher speed tending to occur near the coast. The meander located at 73°W and 37°N in Figure 7-8 moved with an apparent speed of almost 8 n.mi. per day during the seven intervening days, while the next meander toward the northeast moved at about half that rate. In view of the downstream size amplification of the meanders, this result seems quite reasonable.

The next usable pass occurred 13 days later (pass 2208). Figure 7-13 shows this analysis where only the last two meanders are detectable. Comparison with Figure 7-12 indicates a 4 to 5 n.mi. per day movement of both these meanders.

The final analysis (Fig. 7-14) reveals only a short portion of the Gulf Stream boundary as recorded on pass 2222 on 29 October. No direct correlation could be found between these individual meanders and those evident in the western portion of the 15 October analysis.

The wavelength of the faster moving near-shore meanders ranged from 60 to 100 n.mi., and averaged about 85 n.mi.. Assuming a propagation velocity of 8 n.mi. per day, it is clear that in order to maintain the integrity of the individual meanders when compositing multiple passes, no more than 4 or 5 days of data should be simultaneously processed. Referring back to Figure 7-4, it can be seen that if a 75% area coverage is desired, there is only a little better than 50% chance that this coverage can be obtained in four passes. Relaxing the time or coverage restrictions would of course, significantly improve the chances of success.

In summary, it has been demonstrated that time histories of synoptic scale sea surface temperature pattern changes can be developed from high resolution spacecraft data. The task could be made far simpler if an automated cloud distinguishing technique were available using a multi-spectral high resolution sensor. Gulf Stream meander movements of 4 to 8 n.mi. per day have been observed, with higher speeds occurring near the shore. Due to the higher speed and shorter wavelength of these near-shore meanders, shorter averaging periods must be employed in the data compositing programs.

8. USE OF MANNED OBSERVATIONS IN SEA SURFACE TEMPERATURE DETERMINATION

8.1 Objectives

As has been shown, a desirable feature in the mapping of IR sea surface temperatures is computer recognition and elimination of cloud contaminated data points. Present knowledge of radiometric differences between clear and cloudy regions is as yet insufficient to properly define cloud contamination in all situations. The radiance contrast, in the visible and the IR, between an extensive thick cloud deck and a large clear region is readily discernible in present satellite data. However, this radiance contrast can provide no clear indication of the effects of thin cirroform clouds, or particularly of situations involving scattered cumulus in which the sensor resolution element is only partially filled by clouds. With the data presently available, the identification of these situations is not always possible.

The techniques of using simultaneous measurements in the visible and other spectral regions to establish threshold values for cloud contamination can be optimized only if the characteristics of the transition between clear and cloudy areas are better understood. A clear cut distinction in radiance between cloudy and clear atmosphere does not exist in any wavelength region. However, the trade-off between useful sea surface coverage and the false alarm rate can be optimized if the radiance characteristics of clouds can be determined.

In order to improve current knowledge of these radiance characteristics, interest must be selectively focused on special cloud cover situations. As indicated previously, these include thin cirroform clouds and scattered cumulus. Since these phenomena are essentially targets of opportunity, it would be desirable that measurements and observations be performed by means of a manned satellite. The advantages of manned observation in the conduct of these measurements lies not only in his ability to select the proper targets for observation, but also in his ability to document the situation being observed. With the proper training, his description of the response of the sensors in relation to changing cloud cover situations would be invaluable in subsequent data reduction.

While the primary objective of the proposed measurements is to obtain data to establish better cloud discrimination techniques, a second objective may be achieved through coordination between surface ship stations and the manned satellite.

This is the establishment of calibration functions between satellite values and the conventionally measured sea surface temperatures. The role of the astronaut in this phase of the measurement program is probably not as significant, although his description of the concurrent cloud cover over the ship station would still be useful.

8.2 Measurement and Instrumentation Requirements

The achievement of the experimental objectives as outlined above requires coordinated efforts by the manned spacecraft and by oceanographic ship stations providing the "ground truth" data to aid the interpretation of the satellite observations. Specifically, the following types of measurements and observations are considered to be essential.

Spacecraft Measurements:

- a. Radiometric measurements in a visual wavelength region and in a clear atmospheric "window";
- b. Color movies of the scene viewed by the radiometer;
- c. Voice record of the astronaut's description of the visual appearance of the clouds within the field of view of the sensors.

Oceanographic Ship Station Measurements:

- a. Radiometric sea surface temperature in the same wavelength interval as the satellite "window" measurements;
- b. "Bucket" sea surface temperature as normally measured;
- c. Color photographic record of cloud cover by means of an all-sky camera.

The instrumentation required to achieve these measurements certainly requires no new breakthroughs either in technology or design. With respect to the satellite measurements, the most significant aspect of the equipment design is in the optical coupling of the field of view of the radiometers with that of the camera and the sight through which the astronaut makes his observations at the times of data acquisition. Mechanically, the various sensors should be so linked as to be scanned by a simple manipulative action initiated by the astronaut. A highly desirable feature in the data recording system is the ability to generate event markers at the initiation of the astronaut. This feature would provide time references relating the voice record of the astronaut's description to the changing field of view of the sensors. Furthermore, past experiences with analyses of satellite measurements

indicate that a highly desirable feature in the radiometric design is a means by which the calibration of the sensor can be checked prior to, and subsequent to data acquisition. Systems for on-board calibration built into the sensors or external to the sensors should not be too difficult to design in view of the presence of the astronaut to perform the necessary manipulative actions.

The specification of color photography was dictated by experience in analysis of both color and black and white photographs obtained from space. Color photographs not only make use of brightness contrasts but also of spectral contrasts so that depiction of different features in the field of view is enhanced. This enhancement in the photographs obtained by the astronauts in Gemini and Mercury photography experiments is quite evident.

Shipboard equipment necessary to achieve ground truth observation are available as "off-the-shelf" items, and need not be elaborated.

8.3 Visible Radiometer System

In the design of the various satellite sensors to be used in the proposed experiments, considerable attention must be given to the response of the visible radiometer system. It is this sensor which will ultimately provide the information regarding threshold discrimination. With this in mind, the following simplified analysis is included as an illustration of the expected signal levels.

The actual (isotropic) energy flux density in the interval 0.5 - 0.75 μ m reflected from clouds and clear areas may be derived from the measured effective radiant emittance values of Channel 5 of TIROS VII by the following equation (Fritz, 1954).

$$W = \left(\frac{\bar{W}}{\bar{\phi}} \right) D \text{ Watts - Meter}^{-2}$$

where

W = reflected flux density (assuming isotropic reflectance)
watts - meter⁻²

\bar{W} = Channel V measured effective radiant emittance,
watts - meter⁻²

D = Correction factor for the instrument

$\bar{\phi}$ = Mean instrument response function weighted by the spectral
flux of the sun, i. e.

$$\bar{\phi} \equiv \frac{\int W_{\lambda} \phi_{\lambda} d_{\lambda}}{\int W_{\lambda} d_{\lambda}}$$

where

W_{λ} = spectral solar flux density.

To get some idea of the difference between the reflected flux density from cloudy and clear areas, the measured effective radiant emittance may be converted to albedos, again based on the assumption of isotropic reflectance, since (Wexler, 1964)

$$A = \frac{W}{\bar{W}^* \cos \theta}$$

where

A = albedo, ($1 \geq A \geq 0$)

\bar{W}^* = energy (watts - meter⁻²) received by Channel 5 reflected by a perfect diffused reflector illuminated by the sun at normal incidence.

θ = solar zenith angle.

Therefore, in terms of the albedo, the expected reflected solar flux density would be

$$W = \frac{A D \bar{W}^* \cos \theta}{\bar{\phi}} \text{ watts - meter}^{-2}$$

The total power measured by a satellite photometer may then be computed (again assuming diffuse reflection) by the following equation:

$$P = \left[\frac{A D \bar{W}^* \cos \theta}{\pi \bar{\phi}} \times \frac{\pi \xi^2 R^2}{4} \times \frac{\pi d^2}{4R^2} \right] \text{ watts}$$

where

ξ = plane angle of view of photometer in radians

R = distance from detector to reflecting surface

d = radius of detector surface.

The first term is the reflected intensity in watts - meter⁻² steradian⁻¹. The second term is the area of the reflecting surface intercepted by the photometer beam. The third term is the solid angle subtended by the detector surface. Rewriting this equation as:

$$\frac{P}{d^2 \xi^2} = \frac{(A D \bar{W}^* \cos \theta) \pi}{16 \bar{\phi}} \text{ watts-radian}^{-2} \text{ meter}^{-2},$$

we can derive a set of parametric curves for the design of a photometer system. Figure 8-1 is such a set of parametric curves where $P/d^2 \xi^2$ is plotted against A using θ as the parameter. (The products $d^2 \xi^2$ (meter² - radian²) are the geometric characteristics of the photometer.) These curves are derived based on the values of $\bar{\phi}$ and D for Channel 5 of TIROS VII. Vertical dashed lines have been drawn in the figure to represent possible threshold values for these measurements.

8.4 Astronaut Training

Since the role of the astronaut is primarily that of a qualified observer, his training should be an integral part of the experimental planning. The objective of the training should be directed towards sharpening his observation and reporting capabilities. To this end, the use of visual simulation techniques is advised. Color photography of different types of cloud cover situations from the Mercury, Gemini and manned Apollo programs exists in sufficient quantity for such a purpose and should be employed.

Figure 8-1 Expected Signal Levels Reflected from Diffused Clouds

9. SUMMARY AND CONCLUSIONS

A detailed knowledge of the sea surface temperature patterns and their variation in time would be of significant benefit to the commercial fisheries, to the military for use in Anti-Submarine Warfare, and to meteorologists for use in long-range weather prediction. To obtain the required density of observations (both in space and time) by shipboard measurements alone would be a practical impossibility. Before optimal use can be made of satellite data, however, techniques must be developed for the automatic elimination of cloud contamination, and for rapid processing of the temperature pattern information.

Using Nimbus II data, a two phase study was conducted. The low resolution, multi-spectral MRIR data were used in the development of data processing techniques, while the high resolution, single spectral region HRIR data were used in the actual measurement of sea surface temperature patterns and their synoptic changes.

Modifications were made to the original Nimbus Mercator Map Programs to accomplish the following:

- a) Extract and map HRIR data points where the recorded temperature is greater than or equal to some preset threshold value. Because the HRIR sensor was a single channel radiometer, this is the only means of internally eliminating cloud contaminated data.
- b) Extract and map MRIR temperature data using the Channel 5 albedo values as clear-cloudy discriminators. This cloud discrimination technique is applicable only to daytime passes.
- c) Extract and map MRIR temperature data using the Channel 1 water vapor absorption temperatures as clear-cloudy discriminators. This technique is primarily used for nighttime cases, but may also be used in conjunction with the daytime albedo discriminator.
- d) Convert temperature values in $^{\circ}\text{K}$ to single digit alphanumeric codes for off-line printing and card punching. The punched cards may subsequently be used to produce color coded analyses using Allied's Digital Color Printer.
- e) Permit the composite mapping of multiple passes for time averaging, or for cases of recurrent partial cloudiness.

It was found that for the optimal detection of cloud contaminated data in daytime passes, a combination of a visible and a water vapor channel threshold should be used. While there are no unique threshold values in any spectral region, a 15% albedo, and a 237°K water vapor temperature cut-off were established through the

application of failure rate versus false-alarm rate considerations. The 237°K Channel 1 temperature cut-off is also applicable to the problem of nighttime cloud discrimination. With the HRIR data, only the temperature values themselves are available to automatically discriminate cloudiness. A 280°K temperature threshold is suggested, although the failure rate may be uncomfortably high due to the inability to detect certain cloud forms such as high thin cirrus or low warm fog and stratus.

In the planning of remote measurement experiments in oceanography, as well as in other fields, some consideration must be given to the problem of intervening cloud cover. Depending upon climatological conditions and upon the time variation of the phenomena to be observed, certain proposed experiments may have a very low probability of success, or even be totally infeasible. As an example of the application of these considerations, Monte Carlo pass simulation programs were run for the Gulf Stream region, drawing upon information from a world-wide cloud data bank. Graphs of area coverage versus the probability of that coverage were generated as a function of the number of passes at established time intervals. Among other things, these graphs reveal that it may be unrealistic to hold out for very high cloud-free coverage. An analysis of the data from a sequence of MRIR passes essentially verified the computer derived statistical predictions.

A time history of the Gulf Stream meander movement for the month of October 1966 was developed using the nighttime HRIR data. On the whole, the determined meander speeds were in agreement with those values found in earlier conventional surface ship observations. Near-shore meanders were found to propagate downstream at a rate of about 8 n. mi per day. The larger meanders toward the northeast propagated more slowly at rates of 4 to 5 n. mi per day.

Present knowledge of radiometric differences between clear and cloudy regions is as yet insufficient to properly define all cloud contamination situations. Areas of small scattered cloudiness or cirrus clouds may still present considerable difficulty. In order to improve current knowledge of these radiance characteristics, interest must be selectively focused on special cloud cover situations. The advantages of manned observations lie in man's ability to select the proper target for observation, and to document the situation being observed. The types of measurements needed were outlined, and possible equipment configurations were discussed.

Until it is possible to accurately account for the effects of atmospheric attenuation in the satellite data it will be necessary to utilize the temperature gradient information only. It is recommended that ways be sought to meld cloud-free satellite derived temperature gradients with conventional surface ship reports to

produce daily SST maps. Such an operational procedure should probably be conducted by the Fleet Numerical Weather Facility in California. Ways must also be sought to account for the spatial variation of atmospheric attenuation before meaningful analyses can be developed. Possible data sources include FNWF's 12 hourly analysis of the atmospheric mass structure, or some on-board radiometer designed to infer the vertical humidity structure.

It is now felt that the operational use of satellite measured sea surface temperature data is within reach. Most of the problems associated with the detection of cloud contamination in day and nighttime data have been investigated and resolved. Techniques for melding gradient data with absolute values already exist. The effects of atmospheric attenuation on the temperature measurements are understood. A reliable humidity data source is still lacking, but new sensors and techniques are currently being developed. The ability to measure sea surface temperature patterns and to trace their development has been demonstrated. Future efforts should be directed toward the realization of an operational satellite/ship sea surface temperature measurement system.
